

The similarity family is internally redundant; the structural family is not

Each measure has a PROFILE: its detection strength on each of the twelve defects, so twelve numbers. Correlating two profiles gives one point above. Nine structural measures give $9 \times 8 / 2 = 36$ pairs, seven similarity measures 21, and the two families crossed $9 \times 7 = 63$. Comment density is excluded: no injection touches comments, so its profile is flat and has no correlation to take.
